Lame's Constant, $\mu$
Bulk Velocity of Propagation, $c_{1}$
$0.88 \mathrm{cal} / \mathrm{g}-{ }^{\circ} \mathrm{C}\left(0.21 \mathrm{~J} / \mathrm{g}-{ }^{\circ} \mathrm{C}\right)$
$1.05 \mathrm{~g} / \mathrm{cm}^{3}$
$4.1 \times 10^{-5} /{ }^{\circ} \mathrm{C}$
$2.24 \times 10^{10} \mathrm{dyn} / \mathrm{cm}^{2}$
$10.52 \times 10^{3} \mathrm{dyn} / \mathrm{cm}^{2}$
$1.46 \times 10^{5} \mathrm{~cm} / \mathrm{s}$

If we choose the median of these two curves, it can be seen that, for a guinea pig $(a=2 \mathrm{~cm})$, the predicted fundamental frequency is 45 kHz , which is close to that measured by Chou et al. [1975]. For a typical cat ( $a=3 \mathrm{~cm}$ ) the measured cochlear microphonic frequency is 38 kHz . Figure 1 shows a computed frequency of 30 kHz . The computed frequency for an infant ( $a=5 \mathrm{~cm}$ ) and an adult human being ( $a=7 \mathrm{~cm}$ ) are 18 and 13 kHz , respectively. Although experimental data that are directly applicable to this case are not available, related results have indicated that a necessary condition for auditory perception by adults seems to be the ability to hear sounds above 5 to 8 kHz [Frey, 1961; Rissmann and Cain, 1975] .

Fig. 1. Predicted fundamental frequency of vibration of a spherical head in a pulse-moderated microwave field.

### 3.2. Peak pressure and displacement.

Extensive numerical computations have shown that, although the resultant waveforms are qualitatively similar, both pressures and displacements that are computed on the basis of the constrained-surface formulation are consistently higher than those calculated using the stressfree expressions. Moreover, better agreement between theory and experiment exists for the constrainedboundary formulation. The following presentation is therefore specifically related to the constrained-boundary expressions given by equations (13) to (20).
Figures 2 and 3 show the peak pressure and displacement at $r=0,1$ and 2 cm for a sphere of $2-\mathrm{cm}$ radius that stimulates the head of a guinea pig under $2450-\mathrm{MHz}$ radiation. In this case the approximate microwave absorption pattern is obtained by setting $N=3$. These waveforms are evaluated for $t_{0}=10 \mu \mathrm{sec}$. It is seen that the pressure is the highest at the center of the head and has a maximum value of 4.08 dyne $/ \mathrm{cm}^{2}$ for a peak absorption rate of $1 \mathrm{~W} / \mathrm{g}$ (which corresponds to a power density $445 \mathrm{~mW} / \mathrm{cm}^{2}$ of incident energy [Johnson and Guy, 1972]) at the end of the pulse and then oscillates around a constant average value in the absence of elastic damping. As expected, the displacement is zero both at the center and at the surface of the sphere for the constrained-boundary condition. The peak displacement at $r=1.0 \mathrm{~cm}$ is about $2.16 \times 10^{-13}$ meters. Note that a high-frequency component is superimposed on top of the fundamental frequency, which correlates perfectly with that shown in Figure 1.
The peak pressure and displacement at $r=0,1.5$ and 3.0 cm for a $3-\mathrm{cm}$ sphere, which simulates the head of a cat exposed to $2450-\mathrm{MHz}$ radiation, are illustrated in Figures 4 and 5. In this case the approximate microwave absorption pattern is obtained by setting $N=6$. Again, the pressure is the highest at the center, and has a value of 3.69 dyne $/ \mathrm{cm}^{2}$ for a peak absorption rate of $1 \mathrm{~W} / \mathrm{g}$ or $589 \mathrm{~mW} / \mathrm{cm}^{2}$ of incident energy. Quantitative comparisons with two series of experimental threshold determinations [Guy et al. 1975; Rissmann and Cain, 1975] indicate that the computed threshold is extremely close to the measured ones [Lin, 1977b]. The displacement in the model of the cat's head is about $1.51 \times 10^{-13}$ meters. The fundamental frequency of oscillation ob-
